Abstract

This paper investigates whether long-term human capital outcomes are affected by the duration of maternity leave, i.e. by the time mothers spend at home with their new-born before returning to work. Employing Regression Discontinuity and Difference-in-Difference approaches, we exploit an unanticipated reform in Austria which extended the maximum duration of paid and job protected parental leave from 12 to 24 months for children born on July 1, 1990 or later. We use test scores from the Austrian PISA tests of birth cohorts 1990 and 1987 as measure of human capital. The evidence suggest no significant overall impact of the extended parental leave mandate on standardized test scores at age 15, but that the subgroup of boys of highly educated mothers have benefited from this reform while boys of low educated mothers were harmed by it.

JEL-codes: J13, J24, J22

KEYWORDS: parental leave reform, maternal employment, human capital, child development, cognitive skills

1 Introduction

This paper investigates whether prolonged paid and job protected parental leave has effects on the offspring's cognitive development. The main potential channel is reduced maternal employment in the second year of a child's life that has likely increased maternal time for child-rearing. In many industrialized countries, the provision of parental leave is one of the main policy instruments aimed at helping young families reconcile working life with family life. This topic has become increasingly important and prominent in the public debate as female labour force participation rates have been growing over the past decades in many industrialized countries. While proponents of (more generous) parental leave entitlements assert positive consequences for the health and well-being of children and their mothers as well as for the position of women in the workplace, opponents fear that parental leave mandates diminish market flexibility, thereby leading to inefficiencies and lower rates of employment growth (Ruhm 1998, 2000).

The lack of an academic and societal consensus about the potential effects of parental leave on maternal labour market performance and on the development of new-borns is also partly reflected in the large cross-country variation in the generosity of parental leave entitlements in terms of duration of job protection and income replacement level.¹ Since the length of the granted parental leave is relevant for the return-to-work decision, these cross-country differences in legislation help to explain why new mothers in some countries return to work much sooner and spend less time at home with their child compared to mothers in other countries (Ruhm 2000; Tanaka 2005).

Overall, previous empirical studies in psychology and economics have produced mixed evidence regarding the impact of early maternal employment on child outcomes. If anything, the majority of studies seem to support the hypothesis that the labour force participation of mothers during their children's *first* year of life has potentially adverse effects on their subsequent development (Ruhm 2008). In addition, there is some indication for heterogeneous effects across subgroups: children from higher socio-economic backgrounds are potentially more likely to be *negatively* affected by maternal employment, while children from low income families might *benefit* if maternal employment raises family income (Currie 2005). Hence, depending on the specific design of the laws regarding the length of granted leave, the income replacement level during the leave period as well as the medium- to long-term labour market consequences for the mother, parental leave mandates might affect child outcomes through time effects (more maternal time investments) and potentially through income effects (if household income is reduced due to foregone wage earnings of the mother in the short-run and potentially in the long-run).

The difficulty in estimating the causal effect of early maternal employment on child development is that maternal employment, fertility behaviour and the timing of labour market re-entry

¹ For instance, the US federal Family and Medical Leave Act (FMLA) from 1993 grants a maximum duration of unpaid, job protected leave of 12 weeks (Berger et al 2005). The FMLA regulations apply to only about half of the female workforce; parental leave for the other half is determined in individual employer regulations. In contrast, most European countries provide much longer durations of job protected maternity and parental leave (some of which is even compulsory) with partial or full income compensation (Neyer 2003).

after childbirth are choice variables and might be driven by unobserved mother or child characteristics (e.g., ability, fertility and work preferences, role models, regional differences in availability and costs of alternative child care). If particular types of women return to work sooner than others, differences in child outcomes between these groups of mothers might reflect differences in maternal characteristics and intergenerational transmission of ability rather than the causal effect of maternal employment. Reverse causality might be an additional problem, since certain health conditions of a child are likely to impede its mother's return to work.

This study analyses the effects of duration of maternal time at home on long-term cognitive child outcomes in Austria by using an unexpected and unanticipated policy reform that extended the maximum duration of job protected and paid parental leave by twelve months for all eligible mothers giving birth on July 1, 1990 or afterwards. Employed women having a child before this cut-off date were only eligible for job protected and paid parental leave until the child's first birthday while those giving birth afterwards were granted parental leave until the child's second birthday. As the reform was announced at relatively short notice, parents could not adjust their fertility plans in order to benefit from the more generous regime. The reform had a strong impact on the time new mothers stayed at home before returning to work since (a) female labour force participation in Austria in 1990 was already comparatively high, (b) most employed women generally satisfied the eligibility criteria, (c) take-up rates were extremely high and (d) most mothers exhausted the full duration of their leave entitlements (about 80 percent of mothers) (Lalive and Zweimüller 2009; Lalive et al. 2014). However, although the reform caused mothers to substantially delay their return to work in the short-run, it did not adversely affect medium- or long-run employment and earnings of mothers (Lalive and Zweimüller 2009; Lalive et al. 2014).

The aim of this paper is to assess the effect of this twelve-months expansion of paid and job-protected parental leave in the child's second year of life on cognitive skills of affected children, measured at age 15 by test scores from standardized assessments in mathematics, reading and scientific literacy from the international PISA study (Programme for International Student Assessment). The main empirical strategy is based on a Regression Discontinuity (RD) and a related Difference-in-Differences (DID-RD) which exploit the variation in the duration of parental leave created by the specific cut-off date of the reform.² Specifically, we first compare differences in average test scores of children born shortly before and shortly after the reform (born in May/June 1990 versus July/August 1990, respectively). Secondly, we compare these differences with the test score

² The majority of previous studies dealt with the endogeneity problem of the maternal return-to-work decision by including as pre-birth controls, by estimating family fixed effects models and comparing sibling differences, by implementing propensity score matching or by employing instrumental variable techniques (Blau and Grossberg 1992; Currie 2005; Almond and Currie 2011; Hill et al. 2005). As Currie (2005) notes, each of these studies has severe limitations for causal inference and conclusions drawn from single studies have to be put in specific context and compared to results using other methods. A few recent papers try to tackle the identification problem by exploiting exogenous changes in parental leave mandates (Baker and Milligan (2010, 2015) focus on Canada, Carneiro et al. (2015) and Dahl et al. (2013) on Norway, Dustmann and Schönberg (2012) on Germany, Liu and Nordstrom Skans (2010) on Sweden, Rasmussen (2010) on Denmark).

differences in a control year in which there was no reform (children born in May/June 1987 versus July/August 1987). The inclusion of an additional pre-reform control year is motivated by the fact that outcome comparisons across birth months within a given year could be confounded by season of birth or simple age effects (older children being more potentially advantaged at any given test date).

This study contributes to the existing literature in several ways: First, in comparison to the previous quasi-experimental studies, the Austrian reform assessed in this paper is by far the most extensive and generous as it offered 12 additional months of paid and job protected leave. Since eligibility rates were very high and take-up was almost universal, this massive extension of the parental leave period might thus have a stronger impact on child outcomes. Moreover, only a few papers have assessed the effect of maternal care during the child's *second* year of life.³ Second, in contrast to the study for Germany by Dustmann and Schönberg (2012) which comes closest to the Austrian case in terms of cultural and institutional background, this analysis contains information on parental background and can thus distinguish between heterogeneous effects across subgroups, a distinction to be shown as very important. Third, the analysis sheds light on the causal relationship between maternal employment in the first years of the child's life and the child's cognitive development in a country where most non-parental child care of under three-year-olds is provided informally, for instance, by grandparents, instead of formal day care centres (in contrast to countries like Sweden and Denmark where children participate in formal care-centres already at very young ages). Against this background, the reform most likely caused a replacement of informal care through maternal care, which might have different implications than switching from formal to maternal care.

The overall effect of this large parental leave extension on test scores for the pooled sample of all children is close to zero and statistically insignificant, in line with most of the previous quasi-experimental studies from other countries. However, the subgroup analyses by maternal education and child gender points to significant positive reform effects for children of highly educated mothers, especially for boys. In contrast, schooling outcomes of children from lower educated mothers seem to have been harmed (boys have lower test scores and girls have a higher likelihood of being in a lower grade). Hence, in an institutional setting with no formal child care system for very young children, early maternal employment of highly educated women might have detrimental effects for their offspring.⁴ To what extent such potential negative effects can be mitigated or reversed through a high-quality formal day care system is an open question.

³ In contrast to the Austrian reform in 1990, which extended maternal time at home on average by 7.9 months (Lalive et al. 2014), the two other existing studies on parental leave extensions in the second year affected maternal time at home to a much lesser extent. In particular, Dustmann and Schönberg (2012) analyse an unpaid parental leave extension from 18 to 36 months which increased maternal time at home, on average, by 1.4 months. Liu and Nordstrom (2010) focus on a paid leave extension from 12 to 15 months which was implemented gradually by 30 days in each of three consecutive months.

⁴ This effect heterogeneity of parental time with respect to parental socioeconomic status has been also found in studies investigating the effect of TV watching on test scores. For the US, Gentzkow and Shapiro (2008) show that children from households with the least parental human capital benefit most from television as the in-home learning environment in these households, in particular regarding language and vocabulary, is comparatively

The paper is organized as follows: the next section introduces the underlying theoretical framework and highlights and compares the findings and setup of previous quasi-empirical studies of early maternal employment on child outcomes. This is followed by an overview of the institutional background in Austria in Section 3. The section includes details of the Austrian reform as well as a summary of findings from previous studies which evaluated this reform with respect to labour market and fertility outcomes. Section 4 explains the identification strategy and discusses critical assumptions and empirical challenges. Section 5 describes the data and outcome variables. The results of the main specification are presented and discussed in Section 6, while Section 7 contains several robustness checks and sensitivity analyses. Section 8 concludes.

2 Parental Leave, Maternal Employment and Child Development

2.1 The role of maternal employment in the cognitive ability production function

It is helpful to structure the discussion and analysis of potential effects of maternal employment on child outcomes using the following cognitive ability production function (Bernal and Keane 2011; Dustmann and Schönberg 2012).

$$Y_{it} = Y_{it}(T_{it}, G_{it}, C_{it}, F_{it}, P_{it}, \omega_i) \quad (4.1)$$

Cognitive ability of child i at age t (Y_{it}) is determined by several inputs, namely maternal (parental) time investment, T , up through age t , market-purchased goods and services other than non-parental child care, G , which depend on family income (examples are quality of housing, additional educational material, nutrition, health expenditure), time investment through non-parental caregivers, C , (i.e. time in non-parental child care), any direct effect of family composition, F , e.g. number of siblings (interaction between siblings; quantity-quality trade-off), birth order, time intervals between siblings, public investments in children and child development, P , (e.g., early child development programmes, public child care facilities and schools, state child health programmes and health insurance) and an idiosyncratic ability endowment, ω , e.g., through intergenerational transmission of genes. As the function differentiates between different child ages it allows for varying effects of certain inputs at particular stages of child development.

In this framework, there is a clear trade-off between maternal time investment and maternal earned income which could be used to buy market-based inputs. It is possible that the reduction in maternal time inputs of working mothers can be at least partly compensated by other goods (e.g., health investments, better nutrition) or by higher quality time investments of other caregivers. Generally though, the time-income trade-off can be mitigated to the extent that mothers receive compensating parental leave payments while on leave.

Several potential mechanisms through which increased maternal time might positively affect child development are discussed in the literature. One is prolonged breastfeeding which could lead to

poor. Hence, the treatment effect also depends on the type of activity or child care arrangement that is being crowded out by the additional parental time.

better health outcomes of children (Baker and Milligan 2008).⁵ Increased maternal care time might improve children's cognitive development by improving their health, for example, by better monitoring of their health status and more timely doctor visits (Berger et al. 2005), by preparing healthier meals and lowering risk of injuries and infectious disease (Morrill 2011). Early maternal employment, especially when exceeding 10 hours per week, might also negatively influence the attachment of mother and child and might lead to children's behavioural problems (Brooks-Gunn et al. 2002). It is also possible that the physical burden of market-based work leaves mothers with less energy for stimulating and nurturing their children (Ruhm 2004; Waldfogel, Han and Brooks-Gunn 2002). The effect of increased maternal time on child development also crucially depends of the relative quality of the alternative formal or informal child care (Bernal 2008; Bernal and Keane 2011).⁶ As regards informal child care, for instance, evidence for the U.S. and for the UK suggests that children are harmed by early maternal employment (in the first 18 months) if they are being cared for by grandparents, other relatives or friends (see for example the following studies which present more carefully identified evidence: Bernal and Keane 2011; Gregg et al. 2005). Conversely, a prolonged absence from work might raise the risk of social detachment and of depressions by mothers who stay at home, which in turn lowers the quality of maternal time and might have adverse effects for children (Baum II 2003).⁷

2.2 Empirical evidence

All recent studies exploit an unexpected extension of the granted parental leave duration which significantly increases the time mothers stay at home before returning to work after childbirth.⁸ Most of these studies find either no or only negligible effects of prolonged parental leave on cognitive child outcomes.⁹ One exception is Carneiro et al. (2015) who find for Norway significant positive effects of prolonged maternal time at home during the child's first year on high school completion, college attendance and earnings at age 30. While the positive effects on school completion are stronger among children of mothers with low education, the positive earnings effects are particularly pronounced among children of more educated mothers. Liu and Nordstrom Skans (2010) report for Sweden a zero average effect based on the whole sample but positive effects for children of better-educated mothers. Interestingly, we in this study also find zero average effect but large and

⁵ However, despite a significant impact of prolonged parental leave entitlements on breastfeeding duration in Canada, most of Baker and Milligan's (2008) results do not reveal any positive health effects for children.

⁶ In general, identification of the causal effect of different types of child care on child outcomes is complicated due to the diversity of care arrangements and the selection of families into particular forms of child care.

⁷ In this simplified framework we implicitly hold partner's labour supply and child care input constant. This assumption is less restrictive in countries where the bulk of parental child care is traditionally supplied by the mother and family life follows the 'male bread-winner model' as in Austria in 1990.

⁸ See Table 1 in the Online Appendix for a summary of these studies and their findings.

⁹ Note, that in these discontinuity studies, children born shortly before a reform cut-off date will also be indirectly affected by reduced maternal employment during their childhood as their mothers will stay home longer with their younger siblings (born after the reform). Such a positive effect on educational outcomes of older siblings has been documented in Bettinger et al. (2014) for Norway. To the extent that more recent maternal time investments play an important role for schooling outcomes, this indirect co-treatment of control children might help explain these zero findings.

significantly positive effect for children of highly educated mothers. In order to reconcile these seemingly contradictory findings it is important to highlight the essential differences between these studies which complicate straightforward comparisons. The analyses vary predominantly with respect to: (1) *The affected age group of children*: Does the particular extension of parental leave allow women to stay at home longer during the first year of life (e.g., an extension from 8 to 12 months) or does it affect the period when the child is more than two years old? This point is highly relevant if the importance of maternal care varies over the different development stages of the child. (2) *The length of the extension*: The analysed parental leave extensions vary between six weeks and 18 months. The granted length of the extension is likely to influence the additional time that mothers stay home. If there is a positive effect of maternal time on child outcomes and this effect is increasing with time input, then one would expect differential effects depending on leave duration. (3) *The measure of cognitive development and age at its measurement*: While some studies focus on short-run effects measured before the first birthday (parent-reported assessments or psychological tests), others compare medium- or long-term outcomes up to age 30 (e.g., using completed educational attainment or earnings). (4) *Different institutional environments*: There are strong differences across countries (and over time) in terms of prevailing non-parental child care arrangements (formal centre-based or informal care by relatives) which determines the type of care likely to be substituted by prolonged maternal care. (5) *The type of reform and any indirect effects on other supposedly relevant determinants of child outcomes like income and fertility*: e.g., does the reform expand the duration of fully, partly and/or unpaid leave? These indirect effects could alter the (opportunity) costs of children and also enhance or change the ‘quantity-quality’ trade-off. (6) *The precision of the data and the estimations*: Can eligible mothers be identified (only possible in the Norwegian study) or can children be linked to parents? Are the studies based on representative surveys or administrative datasets? (7) *The estimation strategies*: the exact implementation of the DID and RD estimations differs across studies as do the control groups.

To sum up, the institutional background and the details of the reforms vary widely across countries and seem to play an important role for the effect of parental leave on child outcomes. In terms of institutional and cultural set-up, Austria comes closest to Germany, while the type of reform (*paid* leave extension between the child’s first and second birthday) is more similar to the evaluated reform in Sweden where, however, participation rates of one- to two-year-olds in formal child care are very high. Nevertheless, the reform in Sweden led only to a three months extension of parental leave, while in Austria the extension comprised 12 months. This way the analysis in this paper helps to shed more light on the influence of maternal employment beyond the child’s first birthday when formal day care for this age group is generally not available. Furthermore, the Austrian reform is unique in that it involves an exceptionally long extension of paid parental leave.

3 Institutional Setting and Background

The history of parental leave in Austria dates back to 1957 when working women became entitled to an unpaid, but job protected leave of up to six months on top of the paid mandatory maternity leave of 12 weeks, making Austria the first country in Europe to introduce parental leave (Neyer 2003).¹⁰ 1974 saw an introduction of a monthly flat-rate cash benefit to all mothers on parental leave. In 1990, the amount of the regular flat-rate parental leave payment was about 340 Euros per month corresponding to 31 (40) percent of gross (net) *median* female earnings (Lalive and Zweimüller 2009).

The empirical analysis will exploit a quasi-experiment that was created by the amendment to the parental leave legislation that came in effect on July 1, 1990 (*Karenzurlaubserweiterungsgesetz, June 27, 1990, BGBl. Nr. 408/1990*). The main aspect of this reform was the extension of the maximal duration of the optional paid and job protected leave from the child's first up to the child's second birthday.¹¹ This extension was only granted to mothers whose children were born on or after the cut-off date of July 1, 1990. There were no 'transition rules' allowing mothers who gave birth before July 1, 1990 to benefit from the new regulations. This increase of 12 months of paid and job protected parental leave is much larger than any of the comparable reforms that took place in other countries and that have been evaluated in terms of child outcomes. The reform was announced and implemented only shortly before it came into effect. Therefore it was not possible for parents to adjust the timing of conception in order to take advantage of the more generous parental leave regime (i.e. there were no anticipatory fertility effects). Theoretically, parents could have tried to manipulate the day of delivery for births very close to the cut-off date by postponing planned caesarean sections or induced births (Lalive and Zweimüller 2009; Lalive et al. 2014). We discuss this point further below. A rough estimate of the overall share of mothers who were eligible for parental leave in 1990 can be attained by calculating the share of mothers on mandatory maternity leave among all mothers. For 1990, this figure is about 77 percent (the corresponding figure in 1987 is 73.8 percent).¹² Estimated parental leave take-up rates of eligible mothers at that time range between 93 and 96 percent (Kreimer 2002).

The fact that the exogenous variation in the duration of the leave entitlement before and after the reform in Austria was effectively determining the length of leave take-up has been demonstrated by Lalive and Zweimüller (2009) and Lalive et al. (2014). Overall, the reform has had a significant

¹⁰ Fathers became eligible for parental leave only as of January 1, 1990. Their entitlement to parental leave was conditional on the mother meeting all eligibility criteria. The take-up rate of parental leave of fathers remained close to zero during the 1990s (0.2 percent in 1990, 1 percent in 1997; BMUJF 1999).

¹¹ In Austria, in 1990, working mothers were subject to a compulsory maternity leave of 8 weeks before and after delivery (job protected leave with 100% replacement of the average net earnings of the preceding 13 weeks). Following this compulsory maternity leave, mothers were entitled to a job protected and paid leave up to the child's first (second) birthday for those born before (after) July 1, 1990. To become eligible for parental leave benefits women had to be in employment subject to compulsory social insurance contributions for at least 52 weeks during the two years preceding the first birth (20 weeks during the most recent year for higher order births). Periods during which women received unemployment benefits were counted towards these minimum work requirements. For women younger than 25 the work requirement was only 20 weeks during the last 12 months.

¹² These calculations are based on numbers in the Austrian Family Report 1999 (BMUJF 1999), p. 152-157.

impact on the time mothers take parental leave after birth. Only about ten percent of mothers return to work immediately after the end of the mandatory maternity leave, i.e. two months after childbirth, and this pattern holds generally true before and after the reform (see Figure 1, Lalive and Zweimüller 2009).¹³ The figure reveals also a jump of roughly 20 percentage points at the time when the legal leave entitlement expires (at 12 months before the reform and at 24 months after the reform). The reform reduced the short term (within two years) return to work by approximately 35 percentage points. The average duration of parental leave take-up and receiving benefits (after mandatory maternity leave) increased from 10 to 20 months and most mothers exhaust the full duration of their leaves (Lalive and Zweimüller 2009; Lalive et al. 2014). As a result, the average time mothers spent continuously at home before returning to work (to the old or a new employer) increased by over seven months (Table A 1 in the appendix summarizes the main effects of the parental leave reform on maternal labour supply and fertility)¹⁴. At the same time, the total number of months worked in the first five years after the child's birth decreased by only a bit more than three months on average. This indicates that while the reform strongly affected the timing of the return to work in the second year of the child's life, the effect on overall work experience was much smaller. The explanation is that even though mothers returned to the labour market much faster prior to the parental leave reform they also left the labour market sooner and had less stable employment (Lalive et al. 2014). The parental leave extension furthermore reduced the number of months spent in unemployment in the first five years (by about three months on average). In the same time period the loss in earned income accumulated to about 3200 Euros. All these effects are remarkably similar for high- and low-wage mothers (the main difference is that high-wage mothers prolong their time at home by almost one month less than low-wage mothers, by 6.7 versus 7.6 months respectively).

Despite these substantial changes in the short-run return-to-work behaviour the parental leave reform did not affect medium-run labour market outcomes of mothers. There are no significant differences between pre- and post-reform mothers in terms of labour supply or earnings after five or ten years (see Table 3 in the Online Appendix; Lalive and Zweimüller 2009; Lalive et al. 2014).

The reform had also a positive and significant impact on fertility outcomes in the short (within three years after the previous birth) and medium-run (after ten years) (Lalive and Zweimüller 2009). However, high-wage mothers seem to have reacted to the extended leave period mainly by changing the spacing between births, but not overall fertility (reducing very short birth intervals and longer intervals at the same time), while low-wage mothers have additionally increased the total number of births in the next ten years. These heterogeneous fertility effects play an important role for the interpretation of our empirical results.

¹³ See Figure 1 in the Online Appendix.

¹⁴ The outcome variable is censored at 60 months. We provide further details and information on how the reform affected labour market outcomes and fertility behavior of mothers in Table A1 in the Appendix and in the Online Appendix (Tables 2, 3 and 4). Lalive and Zweimüller (2009) and Lalive et al. (2014) contain separate results only for women giving birth to the first child (parity 1) and women giving birth to their second child (or a higher birth parity). Since our analysis includes children of all birth parities, we pool the data provided by Lalive et al. (2014) and generate new estimates of labour market outcomes for all mothers.

3.1 Possible mechanisms and effects of the Austrian reform on child outcomes

There seem to be two potential channels through which the 1990 parental leave extension in Austria could have affected child development: first, a ‘quality channel’ which works through the potentially superior quality of maternal care as opposed to alternative, informal forms of child care, and second, the ‘fertility channel’, which works through changes in the fertility behaviour, i.e. the number of children and the spacing between births.

As noted, the parental leave reform in 1990 significantly raised the time new mothers stayed at home from birth until returning to the work. It increased the continuous maternal time at home particularly in the second year of new-born life. Between the first and the second birthday children reach several important developmental milestones: they start to talk, to walk and they become aware of themselves as separate from others (Shelov 2009).

As noted above the reform did not affect medium- to long-run income and labour market outcomes of the average mother. Thus, it is unlikely that the reform exerted a negative effect on child outcomes driven by a decline in income in the medium- to long-term. The leave extension did generate in the short term a small but not long lasting income loss caused by foregone earnings during the additional leave months. However, mothers on leave did not need to pay for external child-care any longer and this reduction in outlays (jointly with the parental leave benefit) partly offset this temporary decline in income. Furthermore, for those women who would not return to work after the child’s first birthday even under the old regime, the prolonged parental leave payments might have even implied a gain in short term income (these mothers would have had either zero earnings or would have taken up unemployment benefits during the second year). In sum, the overall effect of the extended parental leave on disposable household income is probably much smaller than the (small) potential short-run loss in earnings.

At the time of the reform the prevailing form of child care for children under two years of age was almost exclusively informal care provided by grandparents or other persons.¹⁵ Under the hypothesis that maternal care is superior to informal care for very young children, one would expect that the prolonged parental leave period had a positive impact on child outcomes (e.g., Bernal and Keane 2001; Gregg et al. 2005). This could be especially true for better educated mothers if they are able to provide higher quality and more ‘productive’ maternal care, for instance, through better access to knowledge on how to foster cognitive development of children (Grossman 2006). Furthermore, early-life stress might negatively affect cognitive child outcomes (Hedges and Woon 2011). If the return to work and the associated organization of (informal) child care exerts stress on the family, it is possible that the induced postponement of re-entering the labour force—i.e., the timing—has beneficial implications for the parents and their children.

¹⁵ Only about 2.5 percent of children aged zero to two were enrolled in formal day care (own calculations of gross enrolment rates based on birth numbers and children in formal child care; official statistics on early child care are recorded since 1995).

However, the reform has also altered the fertility behaviour of parents. If shorter spacing between births reduces the time and material resources that are allocated to each child, the reduction in average birth intervals, particularly among high-wage mothers, could have negative implications for child development and cognitive outcomes. On the contrary, if the relation between spacing and child outcomes is non-linear, a positive effect of the reduction in extremely short birth intervals (as also observed more often among high-wage mothers) could outweigh a negative effect from the average reduction in spacing. Increases in the total number of births per woman (observed only for low-wage mothers), could work in the opposite direction and diminish or reverse a potentially positive time effect (quantity-quality trade-off). The reform may have also affected marital stability. However, the empirical evidence about the effect of divorce on children's outcomes is mixed across countries (e.g., Gruber 2004; Haveman and Wolfe 1995; Siedler et al. 2010).¹⁶

4 Empirical Approach

Given the unexpected and strict implementation of the prolonged parental leave period for all children born on July 1, 1990 or later, it is possible to use a Regression Discontinuity methodology and also a Difference-in-Differences analysis based on this RD setup (RD-DID) to identify the effect of extended maternal care on child outcomes.¹⁷ The RD-DID regression specifications that we estimate are the following:

$$y_i = \alpha + \beta_1 Post\ June + \beta_2 bc1990 + \beta_3 Post\ June * bc1990 + \theta_m birth\ month + \varepsilon_i \quad (4.2)$$

$$y_i = \alpha + \beta_1 Post\ June + \beta_2 bc1990 + \beta_3 Post\ June * bc1990 + \theta_m birth\ month + \mu X + \varepsilon_i \quad (4.3)$$

y_i is the measure for cognitive child outcome (i.e. test scores from standardized tests), *Post June* is a dummy indicator for children whose birthday is on or after July 1 (July – December) and the coefficient β_1 captures all possible permanent and general differences between children born in the first and the second half of a given year; *bc1990* is a dummy indicator for the birth cohort 1990; the interaction effect between *Post June* and *bc1990* identifies all children whose mothers were affected by the reform and eligible to a longer parental leave – β_3 is the coefficient of interest and measures the treatment effect; to account for possible season of birth effects as well as age effects the regressions include a set of *birth month* dummy variables. To control for possible differences in sample composition over time, equation (4.3) contains additionally a set of parental and other background characteristics (X).

If the assignment into treated (=post reform; 24 months PL) and control group (=pre reform; 12 months PL) is ‘as good as random’, a simple representation of the estimated treatment effect $\hat{\beta}_3$ (estimated by OLS) is

$$\hat{\beta}_3 = (\bar{y}_{1990,post} - \bar{y}_{1990,pre}) - (\bar{y}_{1987,post} - \bar{y}_{1987,pre}). \quad (4.4)$$

¹⁶ In Norwegian maternity leave reform, parental leave did not affect marital stability (Carneiro et al. 2015).

¹⁷ Dustmann and Schönberg (2012) used a similar approach to study the German reform.

This is the difference in average cognitive outcomes (test scores) of children born after versus before the reform (whose mothers were eligible to 24 versus 12 months of paid parental leave respectively) less the difference in outcomes of children born before and after July 1, 1987 who were not subject to the reform. The advantage of this RD-DID approach is that potentially confounding systematic differences between children born before and after July 1 which could otherwise exert a bias are differenced out: First, the test scores used in the analysis stem from tests that took place within a certain month (e.g. April) and children born in January 1990 will be about 12 months older at the time of the test than children born in December 1990. If age in itself has a positive effect on outcomes, any potentially positive effects of the reform will be downward biased, since post-reform children are always younger than pre-reform children. Second, there might be systematic season of birth effects affecting the composition of children and their parents over the year. If certain types of couples are more likely to have babies in particular months of the year this might also impact upon the distribution of test scores across birth months.

An important identifying assumption in this approach is that mothers could not self-select into treatment or control group. This basically requires that mothers could not manipulate the date of childbirth around the cut-off date of July 1, 1990. Lalive and Zweimüller (1999) and Lalive et al. (2014) provide several arguments and evidence in support of this assumption: first, an assessment of newspaper reports about a potential reform of parental leave duration revealed that the public discussion did not start before November 11, 1989 and that it was not clear until April 5 whether and when such a reform would be implemented. This timing of policy decision and implementation makes anticipatory adjustments to fertility plans highly unlikely, especially when taking into account that successful conception and date of childbirths cannot be perfectly controlled and planned by parents. As to the exact date of delivery, it is generally biologically infeasible to delay births with the exceptions of planned Caesarean sections and induced labour.¹⁸ However, an examination of the number of daily births shortly before and after the reform does not reveal a discontinuity or a higher density of births on July 1 or the days after (see Figure 2, Online Appendix). The pattern of daily births between May and August is strikingly similar in the reform year 1990 and in the pre-reform year 1989. Furthermore, in several sensitivity tests Lalive and Zweimüller (2009) and Lalive et al. (2014) demonstrate that their main findings regarding the effect of the reform on labour market outcomes and fertility are robust to excluding from the sample mothers that gave birth shortly before

¹⁸ Indeed, several papers have shown that parents adjust the timing of births as a response to financial incentives. Dickert-Conlin and Chandra (1999) show for the US that parents tend to take advantage of tax savings by giving birth in December rather than January. There is also evidence of postponements of births in order to benefit from introductions of more generous benefits (e.g., Gans and Leigh 2009) assess the introduction of Australia's baby bonus in 2004; Neugart and Ohlsson (2013) and Tamm (2013) analyze the German parental leave reform in 2007). In contrast, for Austria, Brunner and Kuhn (2014) do not find evidence of manipulation of the date of birth as a response to the abolition of the Austrian baby bonus in 1997. Note, that the proportion of Cesarean sections among all births was low in comparison to the United States or Australia: the rate was 12 percent in Austria in 1995 (earliest date available), while it was about 30 percent in Australia in 2004 (Gans and Leigh 2009) and about 23 percent in 1990 in the US (Osterman and Martin 2014).

or after the cut-off date. Nevertheless, we will address the possibility of such self-selection in our robustness tests.

Another assumption is the *common trend* assumption which requires seasonal patterns or age effects to be constant across years. This assumption is less restrictive if the sample is limited to children born very close to the cut-off date which increase the likelihood that these children are very similar in age as well as in season of birth. Another advantage of narrowing the window of birth months before and after the reform would be that these children are more likely to face identical kindergarten and schooling regulations and rules, e.g., the Austrian school year typically runs from September to August. Furthermore, their mothers were exposed to similar macroeconomic conditions and labour market developments. However, this strategy would require a very large data set. Unfortunately, the available test scores data base does not meet this criterion. Hence, given the data at hand, there is a *trade-off* between limiting the analysis on children who are as similar as possible (which would also reduce the likelihood of violating the common trend assumption) and having a sufficiently large sample size. Therefore, we estimate each specification several times while successively narrowing down the window of birth months.¹⁹

Since the data neither allow identifying children whose mothers were actually eligible for the more generous parental leave entitlements nor contain information on actual duration of leave taking of mothers, the estimated effect will represent the intention-to-treat effect of the reform, i.e., the reduced form effect of being eligible to 24 instead of 12 months of parental leave. This intention-to-treat effect will be a lower bound estimate of the effect of prolonged parental leave and maternal care on child outcomes, since it is estimated on the full sample including children of mothers who did not change their behaviour because of the reform. This latter group consists of non-working mothers as well as working mothers, who stop working post-birth for much longer than the granted parental leave period irrespective of the actual legislation, and of mothers who return to work very early irrespective of the generosity of the system, either non-eligible working mothers or working mothers would return to work immediately after the compulsory maternity leave period independent of the additional parental leave provision. Furthermore, the intention-to-treat estimate will represent an overall net effect of the reform combining all possible channels through which the parental leave extension might have affected child outcomes.

In the empirical part we will perform subgroup analyses by educational attainment of the mother for two reasons. First, stratifying the sample by mother's education might yield estimates closer to the actual effect of the reform. Mothers with higher (lower) education have on average higher

¹⁹ Another reason for narrowing the sample window around the cut-off date as much as possible is the proximity of the reform cut-off date to the Austrian school entry cut-off date. All children having their sixth birthday before September 1 are obliged to start school in the same year (typically at the beginning of September). However, until 1999, enforcement of this school entry cut-off date was not strict, conceding some discretionary power to parents regarding the decision whether their child was 'ready' for school or whether it should start one year later. A comparison of the distribution of children in lower than regular grades across birth months for the cohorts 1990 and 1987 (PISA data 2006 and 2003) reveals that this phenomenon is relatively consistent over time which is an important prerequisite for our RD-DID estimation strategy (figures available by the authors upon request).

(lower) labour force participation rates and, hence, a higher (lower) likelihood of parental leave eligibility. We will therefore distinguish between mothers having completed post-secondary or tertiary education, 89 percent of whom participate in the labour force (employed or unemployed) and mothers whose highest educational degree is higher secondary school or less, of whom 78 percent are in the labour force.²⁰ We label these groups as High Educ. Mothers and Low Educ. Mothers, respectively. However, apart from the employment channel, we do not expect maternal education to have any differential effect on the likelihood of eligibility, since – conditional on employment – parental leave eligibility was almost universal (Lalive et al. 2014). Second, as discussed in Section 3, the parental leave extension had heterogeneous effects on fertility and spacing between births of low- and high-wage mothers which in turn might lead to differential child outcomes (quality-quantity trade-off). Furthermore, an analysis of the Austrian time use survey 1992 shows that, all else equal, highly educated mothers devote on average almost one hour more to child care than mothers with compulsory education (Neuwirth 2004). Hence, there might be also quantity differences in time investments between low and high educated mothers (and possibly quality differences).

5 Data

We use in this study data from the OECD's Programme for International Student Assessment (PISA) for Austria. The PISA studies from 2006 and 2003 capture the relevant 'reform' birth cohort born between January and December 1990 as well as the 'control' birth cohort from 1987. Several important features make the PISA data especially suitable for our analysis: first, the PISA data provide results from *standardized tests* of cognitive skills in terms of reading, mathematical and scientific literacy. The focus of PISA is less a pure assessment of curriculum based knowledge, but more an evaluation of general skills needed for adult life and of the ability to apply knowledge to real-life problems. Second, the tests are administered to a nationally representative sample of 15-year old students independent of their current grade level in school. In contrast, other international studies like TIMSS and PIRLS assess students in particular grade levels, e.g. 4th and 8th grade, and are thus not representative for a particular birth cohort. Comparisons of outcomes across birth months would be biased if, for example, the propensity of grade retention or early or late school entry differs between children born closer or further away from the school entry cut-off date. Third, the PISA data files contain important student-reported background information on the student (e.g., gender, birth year and month, nationality, attitudes), the student's parents (educational achievement, nationality, occupational information) and the school (e.g., school programme, location, school size, resources).

However, the Austrian PISA data have also several disadvantages: there is no retrospective information on maternal labour market participation at the time of birth which prevents a clear identification of mothers who were truly eligible for parental leave. Moreover, the Austrian PISA data

²⁰ Numbers calculated based on the Austrian Census from May 1991 (see Table 5 in the Online Appendix).

does not contain available information on exact birth dates which prevents any refinement of the analysis beyond the month level.

To increase the cohesiveness of the data for the analysis we first dropped from the sample students whose mothers are highly unlikely to have been eligible for parental leave or affected by the reform. This included children who were not born in Austria and whose mothers were thus unlikely to work in Austria at the time of the reform in 1990. Furthermore, a few observations had missing information on maternal education. A small number of students *in schools for children with special needs* were also excluded from the sample to increase consistency across students and across years, since these children have a completely different curriculum and were administered special test items.

The variables used in the analysis are described in Table 1. The main outcome variables measuring cognitive skills are test scores in mathematics, reading and science. The test scores in each subject are rescaled by the OECD so that the mean across all participating countries is 500 points and the standard deviation is 100 points.²¹ Two other outcome variables are binary variables indicating i) whether a student is in a lower than the regular grade level given his or her birth month and ii) whether the student is enrolled in a school track giving access to university or college education (academic track).^{22,23} Student's level data includes gender, month of birth, an indicator for school location in an urban area, mother's and father's highest completed level of education, and migration status of the family (whether the family speaks German at home and whether mother and father were born in Austria; the base category are non-German speaking families).

The mean values of the outcome variables and variables of the PISA 2006 and 2003 data are presented in Table 1, separately for children born in May and June and for children born in July and August. The evidence in the table show that there are no significant systematic differences between pre- and post-reform children in 2006, which supports the important assumption that the 1990 reform was unexpected and that there was no systematic self-selection of particular types of parents or families across the cut-off date.

²¹ To ease comparison of results across survey years, the test results were rescaled such that the reading and mathematics reporting scales of 2006 are equal to those in 2003. The test results in science are rescaled such that the mean is 500 and the standard deviation is 100 for the 30 OECD countries participating in PISA 2006 (see OECD 2009, pp. 157-158). However, any general differences in test scores across years and subjects will be accounted for in the analysis by controlling for years and by running separate regressions for each subject.

²² In Austria, students are allocated to different educational tracks after the fourth grade (i.e. at age 10 or 11) which is relatively early compared to other European countries (Schneeweis and Zweimüller 2014). Starting with grade level nine, a further differentiation into specific tracks takes place.

²³ Several countries conduct longitudinal follow-up studies of PISA participants. These studies reveal a significant correlation between PISA proficiency scores and subsequent skills as well as educational and labour market performance even conditional on background characteristics, e.g. in Australia, Canada, Denmark, Germany and Luxemburg (Fischbach et al. 2013; OECD 2010, 2012). Furthermore, in countries participating in PISA, their country's ranking based on these test scores figure out prominently in public debate about corrective measures and policy reforms for the education system. These policy links reflect the wide perception that PISA scores are correlated with future performance, both at the individual and the country level. For example, Hanushek and Kimko (2000) link PISA test score country ranking and economic growth across nations. More recently Hanushek et al. (2015) use PISA test scores to measure human capital differences across states in the US and show that these are related to the current variation in per-capita GDP among US states.

6 Empirical Results

A first graphical impression of the RD-DID setup for all three test subjects is provided in Figure 1. The figure plots average test scores by birth month together with fitted lines of the predicted test scores to the left and to the right of the reform cut-off date (July 1, vertical line) for both, the reform cohort 1990 and the control cohort 1987. Overall, there is a slightly negative trend in average test scores across birth months which could be explained by possible age effects as discussed earlier. Crucial, however, is the fact that there is no jump in test results for children from the 1990 reform cohort born immediately before and after the reform cut-off date. Indeed, for all three test subject, the predicted fits to the left and to the right of the reform date are continuous at the cut-off, suggesting no effect of the parental leave reform on test scores. This zero finding is substantiated by the virtual overlap of the test scores and fitted lines of the 1990 reform cohort with those of the control cohort from 1987 (except for scientific literacy).

Repeating this graphical analysis separately for male and female students produces the same continuous pattern indicating no reform effect, neither for boys nor for girls.²⁴ However, these findings of no average effects for the entire group as well as for the gender subgroups mask quite substantial reform effect heterogeneity with respect to child gender in combination with maternal education. Figure 2 and Figure 3 show the RD-DID graphs for boys and girls, respectively, and differentiate between children of mothers with higher and lower educational attainment. In particular, when focusing on the black fitted line for sons of highly educated mothers born in the reform year 1990 (Figure 2, top panel), it appears that there is a clear positive jump in test scores immediately after the reform. The overall downward sloping curve is simply shifted upward for those children born after the cut-off date. In contrast, the grey fitted lines for the corresponding subgroup of children from the control cohort 1987 are continuous around the cut-off indicating no systematic differences in test scores between children born before and after July 1 in the absence of the parental leave reform. Turning to the lower panel of Figure 2, this pattern is different for sons of mothers with lower educational attainment: the predicted fit for this subgroup shows either no reform effect (mathematics) or a negative, but very small jump in reading and science test scores after the reform. The corresponding grey lines for the 1987 control cohort are once again continuous at the cut-off date. Overall, the graphs in Figure 2 suggest a positive reform effect only for boys of higher educated mothers and a zero or slightly negative effect for sons of less educated mothers. These heterogeneous reform effects with respect to maternal education do not seem to hold for girls, though. None of the separate graphs for girls do show any substantial jumps at the cut-off date (Figure 3).

To test whether the test score gap between June and July children is significantly different from zero, we regress test scores from the three different subjects on a set of birth month indicators with June as the excluded base category (controlling for parental background). The estimated ‘born in July’ coefficients are reported in Table 2 for separate regressions by subject, maternal education and

²⁴ See Figure 3 in the Online Appendix. Separate graphs by maternal education (Figure 4, Online Appendix) reveal a positive jump in test scores at the reform cut-off for children from highly educated mothers.

child gender. The first two columns in Table 2 show the results from the full sample of mothers. As the graphs in Figure 1 suggested the average test scores do not differ significantly between pre- and post-reform children in the full sample and this applies to all three tested subjects. Furthermore, the estimated coefficients change only marginally after controls for parental background are included in the regression (although standard errors become slightly smaller). Comparing the results by gender (columns 1 and 2, middle and bottom panel) reveals that there might be gender differences as the estimated coefficients for boys tend to be positive (but insignificant), while the estimated coefficients for girls tend to be negative.

Restricting the sample to the subsample of children of higher educated mothers (columns 3 and 4) confirms the graphical impression of a positive effect: the estimated effects become much larger and are significantly different from zero (at the five percent level) for reading and science. The separate analyses by gender reveal that the differences are significantly different from zero only for boys. For completeness, the two columns on the right show the respective results for children of mothers with lower educational attainment. Most of the coefficients have a negative sign implying a decline in test scores after the reform; however, none of these effects is statistically significant.

6.1 Regression Discontinuity-Difference-in-Differences estimations (RD-DID)

As a next step, we refine the analysis by estimating RD-DID models in order to take account of potentially confounding age, seasonality and school-entry effects. The results of the main RD-DID estimates of the effect of the parental leave extension on PISA test scores are presented in Table 3 for the full sample (all mothers) and separately by maternal education. The estimation window covers children born two months before and after the reform (May to August). For each of the three samples the first column shows the results without any control variables (columns 1, 3 and 5), while the second column contains results after controlling for background variables to account for potential changes in sample composition across years (and possibly across months). This more refined estimation approach confirms the findings from the simple graphs shown earlier: the treatment effects of the reform (being born post June in the year 1990) are close to zero in the full sample (columns 1 and 2). Adding background controls changes the coefficients slightly, but given the size of the standard errors these differences are not statistically significant.²⁵ The average effect on reading test scores is a little bit larger and negative, but still not significantly different from zero.

In contrast to these neutral findings are the results from the regressions based on the subsample of children of mothers with higher education. The average effect for all three test subjects is significantly positive and of remarkable size, indicating that the extended parental leave period raised test scores by about 22 percent of a standard deviation (a little bit less in mathematics).²⁶ It is possible

²⁵ Standard errors were clustered by school programme, school location and gender to account for the fact that test scores of students in the same programme, location and gender are likely to be correlated and not independent of each other.

²⁶ As a further refinement, we add a set of dummy variables for the different school programs (which are highly correlated with different average test scores). As expected, their inclusion helps to increase the precision of the

that these differences in results between the full sample and children of highly educated mothers are partly related to the different levels of parental leave eligibility (due to differences in labour force participation rates). More importantly though, the results for this subgroup are more likely to show the pure *time and care* effect of the parental leave extension, since the reform did not affect overall fertility or labour market success of mothers with higher earnings in the medium and long-run (proxied here by higher educational attainment). Since the reform affected the continuous time at home much more than actual labour market experience of the mothers, the results might also point towards a beneficial effect of reducing parental stress related to an early temporary return to work. If there were any negative income effects due to reduced labour earnings during the child's second year of life, these seem to be off-set by other positive reform effects. Recall, that the parental leave reform potentially implied an income gain (new benefit payments) for those mothers who would have had zero earnings during the second year of the child's life in the absence of the reform. Furthermore, bearing in mind that the prevailing form of child care was informal, these positive effects are in line with empirical evidence on detrimental effects of care by grand-parents, relatives or friends at very young ages (e.g., Bernal and Keane 2001; Gregg et al. 2005). In comparison, the effects for children of mothers with lower education are generally negative and even statistically significant for the reading test scores. Although the fraction of affected mothers in this group is smaller, it seems that these children have not benefited from the reform. Furthermore, the statistically significant negative coefficients suggests that the heterogeneous reform effects with respect to maternal education are not driven by differential levels of parental leave eligibility, but by other mechanisms. For instance, the negative effect could be attributed to the increased levels of *fertility* of low-wage mothers (as documented by Lalive and Zweimüller 2009) and, hence, to less available resources (time and market goods) per child (i.e. a possible 'quantity-quality' trade-off), to shorter time intervals between births or maybe to a lower quality of maternal time in the sense of ability to foster cognitive child development.²⁷ The relative quality of the alternative child care (formal as well as informal) which was replaced by maternal care might well vary with mother's education. Furthermore, we cannot rule out the possibility that the loss in earnings during the additional leave months had detrimental effects on some children of less educated mothers.²⁸ However, it is important to note that we do not have direct evidence on actual parental leave eligibility, take-up, return- to-work and fertility behaviour of mothers in our data. Hence, we should be cautious about this interpretation and explanation.

estimates. The treatment effects get larger and more significant. However, due to the potential endogeneity of these variables these results are only reported in the Online Appendix, Table 6.

²⁷ This negative effect of the reform stands in contrast to the positive effects of the Norwegian parental leave reform on children of mothers both with lower and higher education (Carneiro et al. 2015). This difference might be related to the changes in the fertility behaviour among the low-wage mothers in Austria. However, as we lack specific information on heterogeneous fertility responses by educational background for Norway, this explanation is only speculative.

²⁸ Yet, we do not think that this explains the negative effect as the reform did also imply a positive income shock for a fraction of mothers who would have not returned to work before their child's second birthday in either case. Hence, for mothers with less education (and lower wages) it is difficult to say whether the average change in income was indeed negative.

To shed more light on potential gender differences regarding the effects of maternal employment on the cognitive development of children, we run separate regressions for boys and girls (Table 4). Even though sample sizes become rather small in this subgroup analysis, the estimates seem to indicate that boys react more strongly to the reform than girls, especially when looking at those with higher maternal education (columns 3 and 4). While both, post-reform girls and boys, have higher test scores on average, only the coefficients for the boys are statistically significant from zero and are almost three times as large as those for girls (the effect on reading and science test scores for males corresponds to about 0.3 and 0.4 standard deviations). These results would be in line with potential differences in needs and in development between girls and boys at very young ages causing boys to benefit comparatively more from maternal vis-à-vis informal care between the age of one and two. For instance, Brooks-Gunn et al. (2002) state that boys seem to be more ‘vulnerable to early stressors’ and react more adversely to non-maternal child care. Similarly, two US studies on the effect of early maternal employment on children’s health outcomes find that boys are more adversely affected than girls (Gennetian et al. 2010; Morrill 2011). As before, the results for the pooled sample are rather small and insignificant (columns 1 and 2) and the results for children of mothers with lower educational attainment (columns 5 and 6) show negative coefficients which are even significantly different from zero for boys in some specifications. The more pronounced effect among boys might also result from differential effect of the program by child gender. For example, it might reflect an interaction of the reform with the generally prevailing child-gender-specific behaviour among Austrian families as suggested from the following evidence. Using the 1991 Census, we find that mothers whose first child is a boy have lower employment rate, more children, and are more likely to be married.²⁹ This evidence implies that at the time of the reform, first-born girls and boys experienced different home environments in terms of maternal employment, presence of both parents, and number of siblings. Each of these aspects can potentially affect child development and might contribute to gender-specific reform outcomes.

Given the trade-off between raising the sample size and the need to keep the estimation window as narrow as possible to reduce the influence of possibly confounding factors, we re-run the regressions symmetrically while gradually reducing the window of included birth months to the left and to the right of the cut-off date (four/three/two months before and after).³⁰ The results in Table 5 are reported separately by mother’s education. The results for children of mothers with higher education (columns 1 to 3) reveal that increasing the sample size symmetrically to the left and to the right of the cut-off leads to positive, but smaller and insignificant coefficients in the pooled sample on boys and girls (top panel). However, the estimated effects for boys remain highly significant and

²⁹ Results are presented in Table 7 in the Online Appendix. We apply the same methodology and specification as Ichino et al. (2014). Our findings for Austria 1991 are in line with evidence for the U.S., the UK and Italy by Ichino et al. (2014).

³⁰ We also estimated our main RD-DID specification as well as the robustness checks and placebo tests using a one-month window. However, especially for our subsample analyses, the sample sizes became too small to derive solid and meaningful results.

positive. Those for girls become much smaller and even switch signs. The results for children of lower educated mothers become less negative (or more positive) the more months are included in the analysis. For this subgroup, most of the results remain negative and become generally insignificant; the strongest effects are still found for boys.³¹

To test whether these results are influenced by children born after the school-entry cut-off date (September 1), who are thus in lower grade levels than students born before September, we alternatively added further birth months only to the left of the cut-off date, while holding the number of months to the right constant (July and August).³² The results change only marginally indicating that the previous results were not confounded by the school-entry cut-off regulation.

6.2 Comparison with effects of other early childhood interventions

Our main results in Tables 3 and 4 indicate that the parental leave reform significantly raised test scores by about 22 percent of a standard deviation for children of mothers with higher educational attainment. The significant subgroup effects for boys of more educated mothers correspond to about 0.34 and 0.44 standard deviations (for reading and science test scores, respectively). To put the magnitude of the effects in context, we compare our estimates to performance gaps in PISA by parental background as well as to effect sizes in early intervention studies and quasi-experimental evidence on the role of parental versus non-parental child care. First, the performance gap between students of mothers with completed tertiary education and students of mothers with completed primary or lower secondary education lay between 0.72 (science) and 0.63 (mathematics) standard deviations in the Austrian PISA test 2006 (OECD 2007). The average performance of students from a less advantaged economic, social and cultural background (bottom quarter of the PISA index of economic, social and cultural status) was about 0.96 standard deviations lower than the performance of students from a more advantaged economic, social and cultural background (top quarter of the PISA index of economic, social and cultural status) (OECD 2007).³³ Furthermore, the gender gap in PISA scores in our sample corresponds to 0.28, -0.37 and 0.16 standard deviations in mathematics, reading and science respectively (male-female gap). One more year of schooling is associated with an increase in PISA performance in the order of 0.22, 0.21 and 0.10 standard deviations for mathematics, reading and science.³⁴

³¹ As a rough check of whether the reform effect was mainly due to replacing informal by maternal care, we re-estimated the regressions from Table 5 excluding students from Vienna, where the proportion of children aged 0-2 enrolled in childcare during the 1990s was much higher than in the rest of Austria. The results in Table 8 (Online Appendix) seem to support this hypothesis: the estimated effects for children of highly educated mothers are slightly larger, while the negative coefficients for sons of low educated mothers get closer to zero. This is what one could expect if the reform implied more of a trade-off between formal versus maternal child care in Vienna with more severe effects for children (especially sons) of mothers with lower education. Excluding this region from the sample should consequently reduce the pronounced negative effect of the reform.

³² For results, see Table 9 in the Online Appendix.

³³ The PISA index of economic, social and cultural status for 2006 was calculated based on the highest educational level and occupational status at home and accounted for cultural and wealth possessions and educational resources at home (e.g., books).

³⁴ The comparison is based on children born in August and September who are in grade levels 9 and 10.

Second, several randomized trials of early educational intervention programs in the United States point towards substantial and long-lasting effects on cognitive skills as well as schooling and social outcomes (Barnett 2011). For instance, the Perry Preschool program in Michigan in 1962 increased math and reading achievements by 0.33 standard deviations at age 14 (positive effects were found through age 27); the Abecedarian Early Intervention Project in North Carolina in 1972 raised IQ by 0.33 standard deviations (at ages 15 and 21) and maths and reading achievements by 0.4 standard deviations (averaged between the ages 8 to 21) (Barnett 2008; Barnett 2011). A meta-analysis of 123 U.S. early educational interventions finds long-lasting cognitive effects of about 0.35 standard deviations (averaged between the ages 5 and 10) and of almost 0.3 standard deviations measured at ages 11 and above on average (Barnett 2011). Similarly, an international meta-analysis of high-quality studies (with either quasi-experimental or randomized study designs) on 30 interventions from 23 low- to high-income countries (excluding the U.S.) reveal average effect sizes of early educational interventions of 0.35 standard deviations for cognitive achievements, 0.41 standard deviations for improvements in schooling outcomes, 0.27 standard deviations for behavioural change and 0.23 standard deviations for health gains (Nores and Barnett 2010). These averages hide a substantial variation in study-specific effect sizes which range, for instance, between -0.05 and 1.43 standard deviations for cognitive achievements (Nores and Barnett 2010). The meta-analysis also reveals that long-term effects (measured at age 7 and above) are not significantly smaller than short-term effects. However, effect sizes tend to be larger for programs aimed at very young children (younger than 3 years). This evidence is in line with the notion that interventions administered very early in life are generally more effective than those at older ages (Cunha et al. 2006). Bearing in mind that the Austrian parental leave reform affected the life of children most intensively at a very young age, the size of the estimated reform effect appears well in the order of magnitude of early life intervention programs in the literature.

Another relevant study for comparison is Carneiro et al. (2015) which shows that the Norwegian parental leave reform raised earnings at age 30 by about 6 percent among children from more educated mothers. This corresponds to about 7 percent of a standard deviation of the earnings distribution at age 30. As the reform increased paid parental leave take-up by 4 months, this implies an increase in earnings by 2 percent of a standard deviation for each additional month of maternal leave. For Sweden, Liu and Skans (2010) conclude that one additional month of parental leave raises test scores at age 16 by about 1.6 percent of a standard deviation. These effects are smaller than what we find for Austria. In contrast, Cools, Fiva and Kirkeboen 2015 find that an introduction of a *paternal* leave quota in Norway in 1993 increased final exam scores from lower secondary school by 4.5 percent of a standard deviation (intention-to-treat effect). The reform raised paternal leave by about 7 days. Scaling up the effect to one month yields an average effect of $(4.5 \times 4.3 \text{ weeks})$ 19.35 percent of a standard deviation. For the subsample of fathers actually taking the leave, however, the effect is much larger and corresponds to about 1/8 of a standard deviation for seven additional days of paternal leave

(or 0.125×4.3 weeks = 0.538 percent of a standard deviation for a month). Bettinger et al. (2014) evaluate the introduction of a Norwegian family policy which granted cash benefits to mothers staying at home with their under-3-year-old children as of 1998. The authors show that while the effect of stay-at-home-mothers on tenth-grade GPA is about 0.02 percent of a standard deviation (ITT), the effect amounts to 150% of a standard deviation in the small group of compliers. For the USA, Bernal and Keane (2011) estimate negative effect of non-parental child-care on child development: one year of non-parental child-care by relatives reduces cognitive achievement test scores at ages 4–6 by about 0.16 standard deviations. The results by Herbst (2013) also point at a substantial negative effect of non-parental child-care on early cognitive ability tests measured at 9 and 24 months of about 0.29 standard deviations. However, in contrast to Bernal and Keane (2011) Herbst’s results suggest that this negative effect is mainly caused by formal and non-relative child care arrangements and that it is larger for children from economically advantaged background.³⁵ Taking this evidence together, the magnitude of our results is sizeable, albeit not out of reasonable range when compared to the quasi-experimental literature on the effect of parental versus non-parental child-care.

7 Robustness Checks and Alternative Outcome Variables

Table 6 presents the results of two placebo RD-DID analyses using our original RD-DID estimation strategy based on the Austrian sample and the 1990 and 1987 birth cohorts, but using May 1, 1990, and September 1, 1990, as pseudo reform cut-off dates.³⁶ In each case, the estimations are based on children born two months before and after the pseudo reform date. None of the estimated placebo effects is significantly different from zero for the sample of boys (irrespective of maternal educational background). Generally, this is also true for the subsample of girls (the exceptions are a significantly negative (positive) coefficient for the reading (science) score of daughters from highly educated mothers, columns 2 and 5). Thus, overall, but especially regarding the male subsample, the placebo tests seem to verify that our main RD-DID results are not confounded by particular patterns in the data and can indeed be interpreted as the causal effect of the parental leave reform.

In further robustness checks we use the German PISA sample as an additional control group participating in both relevant years without being affected by the Austrian parental leave reform in 1990. Germany appears particularly suitable as control region as it is very similar to its neighbouring country Austria in terms of its schooling and tracking system (Schneeweis and Zweimüller 2014) as well as in terms of its child care institutions, cultural values and attitudes towards the role of families

³⁵ Using the variation in kindergarten-entry-age cut-off dates across U.S. states and over time, Fletcher and Kim (2016) find a one month earlier state kindergarten-entry-age cut-off across, increases average state standardized test results by 21.7 and 13.6 percent of a standard deviation in grade 4 for reading and math and by 12.9 percent of a standard deviation in grade 8 (math) and 18.9 in science, 5.1 in reading.

³⁶ Due to several data and sample problems we cannot exploit the other three existing PISA waves for Austria from the years 2000, 2009 and 2012 for further robustness checks and to analyse the common trend assumption. The most important problems with these other PISA waves are, first, a biased sampling frame in the Austrian PISA 2000, second, a stricter enforcement of the school entry cut-off date that affected the birth cohort tested in 2009 violating the common trend assumption, and third, a follow-up parental leave reform in 1996 (with the same cut-off date as the parental leave reform in 1990) which affected the PISA cohort covered in PISA 2012).

and mothers (Neyer 2003).³⁷ Including the German PISA students allows us to perform a Regression Discontinuity embedded in a triple difference estimation (RD-DDD; see Table 10, Online Appendix). Overall, the RD-DDD results confirm our previous findings (the estimated coefficients are even slightly larger in absolute terms).³⁸

Finally, we examine whether our findings might be confounded by self-selection of mothers into the more generous parental leave regime introduced in July 1, 1990. As the Austrian PISA data does not contain information on exact birth dates we cannot identify students born very close to the cut-off date. However, we can analyse whether our main findings hold even if we delete particular observations of children born in June or July 1990 (see Table 12, Online Appendix). First, we examine the consequences of a scenario where the most able students born in July and having the highest test scores were children of mothers who deliberately selected themselves into the more generous PL regime by postponing (planned) Caesarean sections or induced births. We check this possibility first by excluding the top 5 percent of July-born children from the sample and secondly by excluding also the 5% worst performing students who were born in June. This sample restriction simulates a hypothetical sorting around the cut-off date of the most able mothers (and their children) into July and of the least able mothers and their children into June. In these two sample restrictions we expect that the positive estimates for children of more educated mothers will become smaller. In a third robustness check we randomly exclude 5 percent of children born in June and July 2006 (i.e., the two months closest to the cut-off) as we cannot identify children born closest to the cut-off.³⁹ Even though dropping observations based on endogenous outcomes is actually not appropriate, these three sample trimmings help us to examine the robustness of our evidence. In all three cases our main results are robust to the exclusion of these extreme values (which are potentially closer to the cut-off). Even though the estimated coefficients in the regressions for children from high educated mothers become smaller (as expected), they remain significant and the overall pattern is very similar to the original results.

To better understand potentially underlying mechanisms of our main findings we analyse two alternative schooling outcomes. Using our basic RD-DID setup, we test whether the parental leave extension affects the likelihood that a student is i) in a lower than regular grade level given his or her birth month and ii) enrolled in an academic track school (Table 7).⁴⁰ After all, the estimated treatment effect on test scores might partly be driven by these underlying mechanisms. As regards the school track, the estimated reform effects are very small and not significantly different from zero. The same is true for grade retention in the pooled sample and in the subsample for children of higher educated

³⁷ Furthermore, the PISA test language in both countries is German.

³⁸ Re-running the RD-DDD regressions holding the number of post-reform months constant, while extending the number of pre-reform months produces very similar results (see Table 11, Online Appendix).

³⁹ As our sub-samples are small (and become even smaller by excluding observations), we report results based on a sample in which we pooled all three test outcomes for each child and we condition the regression on subject fixed effects.

⁴⁰ As PISA data do not contain information grade repetition or age at school entry we cannot disentangle whether a student is in a lower than should-be grade level due to deferred school entry or grade repetition.

mothers. However, for children of mothers with lower educational attainment the results suggest that the extended leave significantly increased the likelihood of being in a lower than regular grade level. This effect is significantly positive in the pooled sample of boys and girls, but seems to be particularly driven by the reform effect on girls.

8 Conclusions

The objective of this paper is to investigate whether a substantial extension of a paid and job-protected parental leave mandate – from a child’s first to its second birthday – has any long-term effects on human capital of children. What makes the Austrian parental leave reform particularly compelling for such a causal analysis is that it was implemented with a strict and unanticipated cut-off date: only those mothers who gave birth to their child on or after July 1, 1990 became eligible for the more generous 24 months parental leave duration. As a consequence of this unexpected cut-off date the allocation of mothers and their children into treatment (24 months parental leave entitlements) and control (12 months parental leave) group was sharp and quasi random. This exogenous discontinuity in parental leave duration helps to control for the problem of the otherwise endogenous return-to-work decision. Another advantage of this particular Austrian reform is that it did not seem to have had any effects on medium or long-term labour market outcomes of mothers and only a small positive effect on fertility of low-wage mothers.

We use mathematics, reading and science test scores from the standardized PISA test at age 15 (using the cohort born in the year of the reform 1990 as well as a control birth cohort born 1987 which was not subject to the parental leave reform). The results of the RD and RD-DID analyses and several robustness checks reveal that there are heterogeneous effects of the parental leave reform on PISA test scores across subgroups. When using the *full sample*, the estimates suggest no statistically significant causal effects on cognitive skills. This finding for Austria is in line with the results of most of the studies using changes in parental leave mandates to identify the causal effect of early maternal employment on child outcomes. However, when splitting the sample into two groups of mothers with higher and lower educational attainment, interesting findings emerge: for the children of higher educated mothers, we find significantly positive effects of the parental leave extension on the PISA test scores at age 15. This positive result is especially driven by the large and significant effect on boys. We also find negative reform effects for boys of mothers with lower education. These results are in contrast to findings reported in Carneiro et al. (2015) for Norway where an extension of maternal leave during the first 12 months since birth had positive effects for children of mothers both with lower and higher education. Furthermore, Liu and Nordstrom Skans (2010) find positive effects for their assessed parental leave extension in Sweden when restricting the sample to children of mothers with higher education. However, in contrast to Sweden with a well-established formal child care system for under-two-year olds, the reform in Austria took place at a time when formal childcare for very young children was rare. The parental leave reform might have affected child development through various mechanisms. However, the evidence we present in this study suggests that maternal

care of educated mothers is superior to different informal care arrangements for children during their second year of life. The negative effects for children from mothers with lower education might be caused by reduced time and material resources as low wage mothers reacted to the parental leave reform with increased fertility rates and shorter time intervals between births.

Our study thus adds unique and policy relevant evidence on heterogeneous effects of a parental leave extension with respect to maternal educational status. The same is true for gender differences: while there exists some evidence of heterogeneous *health* outcomes of girls and boys with respect to early maternal employment in the empirical literature, the previous evaluation studies of parental leave on *cognitive* child outcomes have not tested or not found corresponding gender effects. Against this background, the presumably stronger effect of the Austrian parental leave extension on boys points to an interesting aspect which should be explored in more detail in future research. Our empirical results – in particular, those for children from mothers with higher educational background – are robust to various sensitivity checks – including triple DID estimates using Germany as an additional control region which was not affected by the 1990 parental leave reform and several placebo tests. Overall, our results suggest that early maternal employment of highly educated women might have detrimental effects for their offspring in an institutional setting with no formal child care system for very young children. Hence, our findings have potential implications for other countries with low supply of formal (high-quality) child care for children below the age of 2.⁴¹ To what extent such negative effects can be mitigated or reversed through a high-quality formal day care system is an open question.

Our findings carry relevant implications for many countries as parental leave systems vary widely across the world in terms of duration, replacement rate and job protection. Furthermore, maternity and parental leave entitlements are a very active policy area and subject to on-going adjustments and extensions. Among OECD countries, the average duration of paid parental leave for mothers increased from 17 weeks in 1970 to over one year in 2015 (OECD Family Database 2016, “PF2.5 Trends in parental leave policies since 1970”).⁴² Parental leave provisions beyond the child’s first birthday are not that uncommon: One third of all OECD countries grant paid leave to mothers of more than one year. About half of all EU countries offer at least 12 months of paid leave, 8 countries – mainly in Central and Eastern Europe – grant birth related paid leave for up to 24 months or longer (Addati et al. 2014; ILO 2016).

⁴¹ In 2011, the average participation rate among 0 to 2 year-olds in 29 OECD countries was about 29 percent, with many countries having a participation rate of less than 10 percent (e.g., Czech Republic, Hungary, Mexico, Poland; according to the OECD Family Database, LMF 1.2 “Employment and maternity rates for mothers with children under 3 years”, 2014). At the same time, the average labour market participation rate of mothers with children in that age group was about 54 percent. Hence, this difference between these two rates points to a gap in publicly subsidized child-care which working parents have to fill by using alternative, informal care arrangements as was the case in Austria in 1990.

⁴² As of 2014, the OECD average duration of paid leave entitlements to mothers amounted to 54.5 weeks (OECD Family Database, Table PF2.1.A., 2015).

Notes: Estimations weighted by individual inverse probability weights provided in the PISA data set. The standard deviations refer to the 2006 data using the pooled sample from May to August. Significance levels are denoted by: ** $p < 0.05$, * $p < 0.1$. "Migration family type 1" indicates families speaking the test language at home and in which at least one of the parents is foreign-born. "Migration family type 2" indicates families speaking the test language at home and where both parents are native-born. The base category are non-German speaking families.

<i>Controls for parental background</i>	-	✓	-	✓	-	✓

Notes: The presented numbers are the estimated effects of ‘being born in July’ as opposed to ‘being born in June’ using the 2006 PISA data. The results in the top panel stem from the pooled sample of males and females, the middle panel from the male and the bottom panel from the female sample. All regressions include children born between May 1 and August 31 and control for birth months (dummy variables) and gender (top panel). The control variables on parental background include dummy variables for mother’s and father’s educational attainment, school location, and migration background. Robust standard errors in parentheses (clustered by school programme, school location, and gender). Estimations weighted by individual inverse probability weights provided in the PISA data set. *** p<0.01, ** p<0.05, * p<0.1. Source: PISA data set (OECD), own calculations.

Notes: Each cell reports the estimated treatment effect from a separate regression. All regressions include dummy variables for month of birth, a year dummy for 2006, a dummy variable for all children born after June. Estimations from columns 1, 2, 4, and 5 include a further dummy variable for all children born between September and December to account for the school entry cut-off date in Austria and an interaction effect of this dummy variable with the year 2006 variable to account for potential general trends in school entry or repetition norms. The control variables on parental background include dummy variables for father's educational attainment, school location, and migration background of the family. Robust standard errors in parentheses (clustered by school programme, school location, and gender). Estimations weighted by individual inverse probability weights provided in the PISA data set. *** p<0.01, ** p<0.05, * p<0.1. Source: PISA data set (OECD), own calculations.

Notes: Each cell reports the estimated treatment effects from separate DID regressions controlling for the standard set of background variables as in the original DID regressions in the main specification (e.g., Tables 3 and 4). The samples consists of children born between May 1 and August 31 of 1987 or 1990. The dependent variables are two dummy variables indicating whether a student is enrolled in a lower than regular grade level given his birth date and whether the student is enrolled in the academic track. Robust standard errors in parentheses (clustered by school programme, school location, and gender). Estimations weighted by individual inverse probability weights provided in the PISA data set. *** p<0.01, ** p<0.05, * p<0.1. Source: PISA data set (OECD), own calculations.

Figure 1: Local Averages by Subject and Parametric Fit (RD-DID graphs)

Notes: Average test scores by birth month plotted for the reform cohort 1990 and the control cohort 1987 (using official individual weights). The vertical line indicates the month of the parental leave reform (July 1, 1990). The curved line shows the predicted fit from two regressions of test scores on birth month and its square based on (1) all observations born between January and June and (2) born between July and December.

Figure 2: Local Averages and Parametric Fit for Boys, by Maternal Education (RD-DID graphs)

Notes: Sample restricted to male students. Average test scores by birth month and mother's education plotted for the reform cohort 1990 and the control cohort 1987 (using official individual PISA weights). The vertical line indicates the month of the parental leave reform (July 1, 1990). The curved line shows the predicted fit from two regressions of test scores on birth month and its square based on (1) all observations born between January and June and (2) born between July and December.

Figure 3: Local Averages and Parametric Fit for Girls, by Maternal Education (RD-DID graphs)

Notes: Sample restricted to female students. Average test scores by birth month and mother's education plotted for the reform cohort 1990 and the control cohort 1987 (using official individual PISA weights). The vertical line indicates the month of the parental leave reform (July 1, 1990). The curved line shows the predicted fit from two regressions of test scores on birth month and its square based on (1) all observations born between January and June and (2) born between July and December.

APPENDIX

Additional birth 17-28 months	0.084*** (0.010)	0.08*** (0.014)	0.089*** (0.014)
Additional birth 29-120 months	-0.021* (0.012)	-0.031* (0.017)	-0.013 (0.017)
Number of observations	6,180	3,087	3,093

Notes: Women earning above (below) the median daily income one year prior to the child's birth are classified as high (low) wage mothers. Women not working one year prior to birth are assigned to the low-wage group. Panel A reports DID-RD estimates for the impact of the 1990 parental leave reform on mother's cumulative labour market outcomes between the child's birth and year 5. The sample includes all mothers giving birth (all birth parities) between May and August in 1990 and 1989 (pre-reform year as control group). The underlying regressions control for age at birth and several pre-birth labour market indicators of the mother as in Lalive et al. (2014). For more details see Lalive et al. (2014). Panel B reports parameter estimates of "July 1990" from linear regressions. The sample covers mothers giving birth to their first child (parity 1) in June or July 1990. For more details on the regression see Lalive and Zweimüller (2009). Further results are presented in the Online Appendix. Robust standard errors in parentheses. *** p<0.01, ** p<0.05, * p<0.1. Source: Panel A: ASSD data and Stata replication-do-file provided by Lalive et al. (2014) for replication purposes (supplementary material to the publication). Own calculations based on the sample for all birth parities. Panel B: Excerpt from Table VI, p. 1391 (Lalive and Zweimüller 2009).
